MULTILEVEL ANALYSIS IN THE STUDY OF CRIME AND JUSTICE

“The most pervasive fallacy of philosophic thinking goes back to neglect of context”

(John Dewey, 1931)

Neither criminal behavior nor society’s reaction to it occurs in a social vacuum – for this reason criminology as a discipline is inherently a multilevel enterprise. Individual criminal behavior is influenced by larger social, political and environmental factors, as are the decisions of various actors in the criminal justice system. Classroom and school characteristics affect adolescent development, misconduct and delinquency (Beaver et al. 2008; Osgood and Anderson, 2004; Stewart, 2003). Family and neighborhood characteristics influence the likelihood of victimization and offending as well as post-release recidivism and fear of crime (Nieuwbeerta et al., 2008; Wilcox et al., 2007; Lauritsen and Sc gum, 2004; Kubrin and Stewart, 2006; Wyant, 2008; Lee and Ulmer, 2000). Police department, precinct and neighborhood factors affect police arrest practices, use of force and clearance rates (Smit, 1986; Sun et al. 2008; Lawton, 2007; Pare et al. 2007; Eitle et al. 2005; Terrill and Reisig, 2003). Judge characteristics and court contexts affect individual punishment decisions (Britt, 2000; Ulmer and Johnson, 2004; Johnson, 2006; Wooldredge, 2007) and prison environments are tied to inmate misconduct, substance use and violence (Camp et al. 2003; Gillespie 2005; Huebner, 2003; Wooldredge et al. 2001). Although these examples cover a diverse array of criminological topics, they all share a common analytical quality – each involves data that are measured across multiple units of analysis. When this is the case, multilevel models offer a useful statistical approach for studying diverse issues in crime and justice. As Table 1 demonstrates, recent years have witnessed an abundance of multilevel studies across a variety of topics in criminology and criminal justice.

This chapter provides a basic introduction to the use of multilevel statistical models in the field. It begins with a conceptual overview explaining what multilevel models are and why they are necessary. It then provides a statistical overview of basic multilevel models, illustrating their application using punishment data from federal district courts. The chapter concludes with a discussion of advanced applications and common concerns that arise in the context of multilevel research endeavors.
CONCEPTUAL OVERVIEW

Multilevel statistical models are necessitated by the fact that social relations exist at several different levels of analysis and jointly influence outcomes of interest. Smaller units of analysis are often “nested” within one or more larger units of analysis. For instance, students are nested within classrooms and schools, offenders and victims are both nested within family and neighborhood environments, and criminal justice personnel are nested within larger community and organizational contexts. In each of these cases, characteristics of some larger context are expected to influence individual behavior. This logic can be extended to any situation involving multiple levels of analysis including but not limited to individuals, groups, social networks, neighborhoods, communities, counties, states and even countries. Moreover, longitudinal research questions often involve multilevel data structures, with repeated measures nested within individuals or with observations nested over time (e.g. Horney et al. 1995; Slocum et al. 2005; Rosenfeld et al. 2007). Other common applications of multilevel analysis include twin studies with paired or clustered sibling dyads (e.g. Wright et al. 2008; Taylor et al. 2002) and meta-analyses that involve multiple effect sizes nested within the same study or dataset (e.g. Raudenbus, 1984; Goldstein et al. 2000). Regardless of the level of aggregation or “nesting,” the important point is that criminological enterprises often involve data that span multiple levels of analysis. In fact, given the complexity of our social world, it can be difficult to identify topics of criminological interest that are not characterized by multiple spheres of social influence. When these multiple influences are present, multilevel statistical models represent a useful and even necessary tool for analyzing a broad variety of criminological research questions.

A MODEL BY ANY OTHER NAME?

Given the complexity surrounding multilevel models, it is useful to distinguish up front what can sometimes be a confusing and inexact argot. Various monikers are used to describe multilevel statistical models (e.g. multilevel models, hierarchical models, nested models, mixed models). Although this nomenclature is often applied interchangeably, there can be subtle but important differences in these designations. Multilevel modeling is used here as a broad, all-encompassing rubric for statistical models...
t at are explicitly designed to analyze and infer relations ips for more t an one level of analysis.¹ T e language of multilevel models is furt er complicated by t e fact t at there are various different software packages t at can be used to estimate multilevel models, some of w ic are general statistical packages (e.g. SAS, STATA) and ot hers t at are specialized multilevel programs (e.g. HLM, MLwin, aML).²

Additional confusion may derive from t e fact t at sc olars often use terminology suc as ecological, aggregate and contextual effects interc angeably despite important differences in t eir meaning. Ecological effects, or group-level effects, can refer to any group level influence t at is associated wit t e ig er level of analysis. Group level effects can take several forms. First, aggregate effects (sometime referred to as nalytical or derived variables) are created by aggregating individual level caracteristics up to t e group level of analysis (e.g. percent male in a sc ool). T ese are sometimes distinguised from structural effects t at are also derived from individual data but capture relational measures among members wit in a group (e.g. density of friends ip networks) (see Luke, 2004: 6). To complicate matters, w en individual level data are aggregated to t e group level t ey can exert two distinct types of influence – first, t ey can exert compositional effects w ic reflect group differences t at are attributable to variability in t e constitution of t e groups – between-group differences may simply reflect t e fact t at groups are made up of different types of individuals. Second t ey can exert contextual effects w ic represent influences above and beyond differences t at exist in group composition. Contextual effects are sometimes referred to as emergent properties because t e collective exerts a synergistic influence t at is unique to t e group aggregation and w ic is not present in t e individual

¹ Hierarc ical or nested models, for instance, tec nically refer to data structures involving exact nesting of smaller levels of analysis wit in larger units. Multilevel data, ower, can also be non-nested, or “cross-classified”, in ways t at do not follow a neat hierarc ical ordering. Data mig t be nested wit in years and wit in states at t e same time, for example, wit no clear hierarc y to “year” and “state” as levels of analysis (Gelman and Hill, 2007: 2). Similarly, adolescents mig t be nested wit in sc ools and neig bor oods wit students from the same neig bor ood attending different sc ools. Although these cases clearly involve multilevel data, they are not hierarc ical in a tec nical sense. Similarly, “mixed models” tec nically refer to statistical models containing both “fixed” and “random” effects. Alt ogether t is often is the case in multilevel models, it is not necessarily the case, so the broader rubric multilevel modeling is preferred to capture the variety of models designed to incorporate data across multiple units of analysis.

² A useful and detailed review of t e strengt hs and limitations of numerous software programs t at provide for t e estimation of multilevel models is provided by t e Centre for Multilevel Modeling at t e University of Bristol at http://www.cmm.bris.ac.uk/learning-training/multilevel-m-software/index.stml.
constituent parts. Alt oug t e term “contextual effect” is sometimes used as a broader rubric for any group level influence, t e narrower definition provided ere is often useful for distinguis ing among types of ecological influences t at can be examined in multilevel models. Finally, global effects refer to structural c aracteristics of t e collective itself t at are not derived from individual data but rat er reflect measures t at are specific to t e group (e.g. p ysical dilapidation of t e sc ool). T ese and ot er commonly used terms in multilevel analysis are summarized in Table 2.

THEORETICAL RATIONALES FOR MULTILEVEL MODELS

T e need for multilevel statistical models is firmly rooted in bot t eoretical and met odological rationales. Multilevel models are extensions of traditional regression models t at account for t e structuring of data across aggregate groupings, t at is, t ey explicitly account for t e nested nature of data across multiple levels of analysis. Because our social world is in erently multilevel, t eoretical perspectives t at incorporate multiple levels of influence in t e study of crime and justice are bound to improve our ability to explain bot individual criminal be avior and society’s reaction to it.

Figure 1 presents a sc ematic of a ypot etical study examining t e influence of low self-control on delinquency in a sample of ig sc ool students. Imagine t at self-control is measured at multiple time points for t e same sample of students. In t at case, multiple measures of self-control would be nested wit in individual students, and individual students would be nested wit in classrooms w ic are nested wit in sc ools. T e lowest level of analysis would be wit in-individual observations of self-control, and t e ig est level of analysis would be sc ool-level c aracteristics. Ignoring t is ierarchical data structuring, t en, is likely to introduce omitted variable bias of a large-scale t eoretical nature.

P ilosop ical discourse on emergent properties dates all the way back to Aristotle but was per aps most lucidly applied by Jo n Stuart Mill. He argued that t e uman body in its entirety produces something uniquely greater than its singular organic parts, stating t at “To w atever degree we mig t imagine our knowledge of t e properties of the several ingredients of a living body to be extended and perfected, it is certain that no mere summing up of t ose elements will ever amount to t e action of t e living body itself” (Mill, 1843). Contextual effects models ave long been applied in sociology and related fields (e.g. Firebaugh , 1978; Blalock, 1984), but these applications differ from multilevel models in t at t e latter are more general formulations t at specifically account for residual correlation wit in groups and explicitly provide for examination of the causes of between-group variation in outcomes.

Table 2 is partially adapted from Diez Roux (2002) w ic contains a more detailed and elaborate glossary of many of these terms.

---

3 P ilosop ical discourse on emergent properties dates all the way back to Aristotle but was per aps most lucidly applied by Jo n Stuart Mill. He argued that t e uman body in its entirety produces something uniquely greater than its singular organic parts, stating t at “To w atever degree we mig t imagine our knowledge of t e properties of the several ingredients of a living body to be extended and perfected, it is certain that no mere summing up of t ose elements will ever amount to t e action of t e living body itself” (Mill, 1843). Contextual effects models ave long been applied in sociology and related fields (e.g. Firebaugh , 1978; Blalock, 1984), but these applications differ from multilevel models in t at t e latter are more general formulations t at specifically account for residual correlation wit in groups and explicitly provide for examination of the causes of between-group variation in outcomes.

4 Table 2 is partially adapted from Diez Roux (2002) w ic contains a more detailed and elaborate glossary of many of these terms.
Moreover, many theoretical perspectives explicitly argue that micro-level influences will vary across macro-social contexts. For instance, racial group theories (Blumer, 1958; Liska, 1992) predict that exercise of formal social control will vary in concert with large or growing minority populations. Testing theoretical models that explicitly incorporate variation in micro-effects across macro-theoretical contexts therefore offers an important opportunity to advance criminological knowledge. Assuming that theoretical influences operate at a single level of analysis is likely to provide a simplistic and incomplete portrayal of the complex criminological social world.

Moreover, inferential problems can emerge when data are used to draw statistical conclusions across levels of analysis. For instance, in this classic study of immigrant literacy, Robinson (1950) examined the correlation between aggregate literacy rates and the proportion of the population that was immigrant at the state level. He found a substantial positive correlation between percent immigrant and literacy rate ($r=.53$). Yet when individual level data on immigration and literacy were separately examined, the correlation reversed and became negative ($r=-.11$). Although individual immigrants had lower literacy, they tended to settle in states with higher native literacy rates, thus confounding the individual and aggregate relations. This offers an example of the ecological fallacy, or erroneous conclusions involving individual relations that are inferred from aggregate data. As Peter Blau (1960: 179) suggested, aggregate studies are limited because they cannot “separate the consequences of social conditions from the consequences of the individual’s own characteristics for behavior, because ecological data do not furnish information about individuals except in the aggregate.”

The same mistake in statistical inference can occur in the opposite direction. The tomistic (or individualistic) fallacy occurs when aggregate relations are mistakenly inferred from individual level data. Because associations between two variables at the individual level may differ from associations for analogous variables at a higher level of aggregation, aggregate relations cannot be reliably inferred from individual level data. For instance, social disorganization theory would predict that crimes rates across neighborhoods are related to mobility rates because high population turnover reduces informal social control at the neighborhood level. Because this prediction refers to neighbor oods as the unit of
analysis, one would risk serious inferential error testing the group-level hypothesis with individual level data. For instance, one could not test the theory by examining whether individuals who move residences have higher criminal involvement. To do so would be to commit the atomistic fallacy. This reflects the fact that variables aggregated up from individual level data often have unique and independent contextual effects. Moving to a new residence represents a different causal pathway than living in a neighborhood with rates of residential mobility.5

Because of the inherent difficulties in making statistical inferences across different levels of analysis, a preferred approach is to use multilevel analytic procedures to simultaneously incorporate individual and group level causal processes. Multilevel models explicitly provide for this type of statistical analysis. The difficulty is in distinguishing among the different types of individual and ecological influences that are of theoretical interest and then specifying the statistical model to properly estimate these effects.

MULTILEVEL MODELING AND HYPOTHESIS TESTING

There are also persuasive statistical reasons for engaging in multilevel modeling, such as providing improved parameter estimates, corrected standard errors, and conducting more accurate statistical significance tests. Utilizing traditional regression models for multilevel data presents several problems. Figure 2 presents a second example of hierarchical data where individual criminal offenders are nested within judges and county courts. Because several offenders are sentenced by the same judge and several judges are within the same courtroom environment, statistical dependencies are likely to arise among clustered observations. When individual data is nested within aggregate groups, observations within clusters are likely to be unaccounted-for similarities. If, for instance, some judges are “hanging judges” while others are “bleeding-heart liberals,” then offenders sentenced by the former will have sentences that are systematically harsher than offenders sentenced by the latter. Statistically speaking, the

5 Two related but distinct problems of causal inference are the psychologistic fallacy, which can occur when individual level data are used to draw inferences without accounting for confounding ecological influences, and the sociologistic fallacy which may arise from the failure to consider individual level characteristics when drawing inferences about the causes of group variability. The psychologistic fallacy results from a failure to adequately consider contextual effects, whereas the sociologistic fallacy results from a failure to capture compositional effects.
residual errors will be correlated, systematically falling above the regression line for the first judge and below it for the second. Because one of the assumptions of ordinary regression models is that residual errors are independent, such systematic clustering would violate this core model assumption. The consequence of this violation is that standard errors will be underestimated by the ordinary regression model. Statistical significance tests will therefore be too liberal, risking Type I inferential errors in which the null hypothesis is falsely rejected even when true in the population. Multilevel statistical models are needed to account for statistical dependencies that occur among clusters of hierarchically organized data.6

A related problem is that statistical significance tests in ordinary regression models utilize the wrong degrees of freedom for ecological predictors in the model. Traditional regression models fail to account for the fact that hierarchically structured data are characterized by different sample sizes at each level of analysis. For example, with data on 1,000 students nested within 50 schools, there would be an individual level sample size of 1,000 observations but a school level sample size of only 50 observations. This means that statistical significance tests for school-level predictors need to be based on degrees of freedom that reflect the number of schools in the data, not the number of students. Statistical significance tests in ordinary regression models fail to recognize this important distinction. The consequence is that the amount of statistical power available for testing school-level predictors will be exaggerated. The number of degrees of freedom for statistical significance tests needs to be adjusted for the number of aggregate units in the data – multilevel models provide these adjustments.

A third advantage of multilevel models over ordinary regression models is that they allow for modeling of heterogeneity in regression effects. The single-level regression model assumes de facto that individual predictors exert the same effect in each aggregate grouping. Multilevel models, on the other hand, explicitly allow for variation in the effects of individual predictors across higher levels of analysis.

---

6 A simpler alternative to the full multilevel model is to estimate an ordinary regression using robust standard errors that are adjusted for the clustering of observations across level 2 units. For example, STATA provides a “cluster” command option that adjusts standard errors for residual dependency. This can be a useful approach when the goal is simply to “control” for clustering, but beyond this it does not provide the same advantages of the multilevel model. Another option is to control for group-level variation using a “fixed effects” model that includes dummy variables for each level 2 unit in the data. This is a useful approach for removing the intraclass correlation due to group dependency, but it precludes examination of between-group differences.
Ulmer and Bradley, (2006), for instance, have argued that the effect of trial conviction on criminal sentence varies across courts. This proposition is illustrated in Figure 3 using federal punishment data for a random sample of 8 districts courts. The ordinary regression model would constrain the effect of trial conviction to be uniform across courts, but Figure 3 clearly suggests variation in its effect across courts. Multilevel analysis allows for this type of variation to be explicitly incorporated into the statistical model, providing researchers with a useful tool for better capturing the real-world complexity that is likely to characterize individual influences across criminological contexts.

Other advantages that also characterize multilevel models are that they provide for convenient and accurate tests of cross-level interactions, or moderating effects that involve both individual and ecological variables. For example, the influence of individual socioeconomic status on delinquency might depend on the socioeconomic composition of the school. This conditional relationship could be directly investigated by specifying a cross-level interaction between an individual’s SES and the mean SES at the school level.

One final statistical advantage of multilevel models is that they are able to simultaneously incorporate information both within and between groups in order to provide optimally-weighted group level estimates. This is accomplished by combining information from the group itself with information from other similar groups in the data, and it is particularly useful when some groups have relatively few observations. Because groups with smaller sample sizes will have less reliable group means, some regression to the overall grand mean is expected. Utilizing a Bayesian estimation approach, the multilevel model shifts within-group mean toward the mean for other groups. The more reliable the group mean, the more easily it is weighted; the less reliable (and the less variability across groups), the more the estimate is shifted toward the overall grand mean for all groups in the data. Thus estimates for specific groups are based not only on their own within-group data, but also on data from other groups. This process is sometimes referred to as “borrowing power” because within-group estimates benefit from information on other groups, and the estimates themselves are sometimes called “shrinkage estimates” because they “shrink” individual group means toward the grand mean for all groups. The end result is
Multilevel models, then, provide numerous analytical and statistical advantages over ordinary regression approaches when data are nested across levels of analysis. By providing for the simultaneous inclusion of individual and group level information, they better specify the complex relations that often characterize our social world, and they help overcome common problems of statistical inference associated with reliance on single-level data. Moreover, multilevel models correct for the problematic clustering of observations that may occur with nested data, they provide a convenient approach for modeling both within and between group variability in regression effects, and they offer improved parameter estimates that simultaneously incorporate within and between group information. The remaining discussion provides a basic statistical introduction to the multilevel model along with examples illustrating its application to the study of criminal punishment in federal court.

**STATISTICAL OVERVIEW**

Multilevel models are simple extensions of ordinary regression models, which account for the nesting of data within higher-order units. It is therefore useful to begin with an overview of the basic regression model in order to demonstrate how the multilevel adaptation builds upon and extends it to the case of multilevel data. For illustrative purposes, examples are provided using United States Sentencing Commission (USSC) data on a random sample of 25,000 convicted federal offenders nested within 89 federal district courts across the U.S.

**FROM ORDINARY REGRESSION TO MULTILEVEL ANALYSIS**

The following equation provides the formula for this weighting process (Raudenbus and Bryk, 2002: 46):

\[
\hat{\beta}_j^* = \lambda_j \hat{y}_{1j} + (1 - \lambda_j) \hat{y}_{00}
\]

where \(\hat{\beta}_j^*\) is the group estimate, \(\lambda_j\) is a product of the individual group mean \(\hat{y}_{1j}\) weighted by its reliability \(\lambda_j\), plus the overall grand mean \(\hat{y}_{00}\) weighted by the complement of the reliability \((1 - \lambda_j)\). If the reliability of the group mean is one, the weighted estimate reduces to the group mean; if it is zero, it reduces to the grand mean. The more reliable the group mean, the more it counts in the multilevel estimate. When the assumptions of the multilevel model are met, this provides the most precise and most efficient estimator of the group mean.

These data are drawn from fiscal years 1997 to 2000 and are restricted to the 89 federal districts and 11 circuit courts in the U.S., with the District of Columbia excluded because it is its own district and circuit court. For more information on the USSC data see Johnson et al. (2008).
When faced with multilevel data (e.g., lower-level data that is nested within some higher-level grouping), ordinary regression approaches can take three basic forms. First, individual data can be pooled across groups and analyzed without regard for group structure. This approach ignores important group-level variability and often violates key assumptions of OLS regression such as independent errors. Second, separate unpoled analyses can be conducted within each group. This approach can be useful for examining between-group variability, but it requires relatively large samples for each group and it is cumbersome when the number of groups becomes large. Third, aggregate analysis can also be conducted at the group level alone, but this approach ignores within-group variability and requires a relatively large number of groups for analysis. In each of these cases, traditional regression approaches are unable to incorporate the full range of information available at both individual and group level of analysis and they may violate important assumptions of the single-level ordinary regression model.

For illustrative purposes, the ordinary regression model is presented in Equation 1:

$$Y_i = \beta_0 + \beta_1 X_i + r_i$$

where $Y_i$ is a continuous dependent variable, $\beta_0$ is the model intercept, $\beta_1$ is the effect of the independent variable $X_i$ for individual $i$ and $r_i$ is the individual level residual error term. Two key assumptions of the linear regression model are that the relationship between $X_i$ and $Y_i$ can be summarized with a single linear regression line and that all of the residual error terms for individuals in the data are statistically independent of one another. Both of these assumptions are likely to be violated with multilevel data, first because the effect of $X_i$ on $Y_i$ may vary by group and second because individuals within the same group are likely to share unaccounted-for similarities.

Failure to account for the nesting of observations can result in “false power” at both levels of analysis. False power occurs because there is typically less independent information available when observations are clustered together. Consider the difference between a) data from 50 schools with 20 students each, versus b) data from 1,000 schools with one student each. The number of students is the same, but if students share similarities within schools, each student provides less unique information in the first sample than in the second. Moreover, there is more unique school-level data in the second...
sample the first. Because ordinary regression models ignore the clustering of individuals within schools, they treat both samples as equivalent. The consequence of this is that the amount of statistical power for the first sample is artificially inflated at both the individual and school level of analysis. Moreover, standard errors for the first sample will be underestimated and significance tests will be too liberal if there are unaccounted-for similarities among students within schools.

The multilevel solution is to add an additional error parameter to the ordinary regression model in order to capture group level dependencies in the data. The multilevel model is represented by a series of “submodels” that model between-group variation in individual level parameters as a function of group level processes. A basic two-level random intercept model is presented in Equation 2:

\[
\begin{align*}
\text{Level 1:} & \quad Y_{ij} = \beta_0 + \beta_1 X_{ij} + r_{ij} \\
\text{Level 2:} & \quad \beta_0 = \gamma_0 + u_{0j}
\end{align*}
\]  

(2)

where the level one intercept \(\beta_0\) is modeled as an outcome in the level 2 portion of the model. The \(\gamma_0\) parameter represents the Level 2 intercept (gammas are substituted for betas at Level 2 for notational convenience) and the \(u_{0j}\) parameter represents a new group level error term, which accounts for group-level dependence. The two-level model specification is presented for simple notational convenience and can be combined into an equivalent single level model by substituting the Level 2 model in for \(\beta_{0j}\) at Level 1. Doing so produces the combined model in Equation 3:

\[
Y_{ij} = \gamma_0 + \beta_1 X_{ij} + r_{ij} + u_{0j}
\]  

(3)

Comparing Equation 3 to Equation 1, it becomes clear that the only difference between the ordinary regression model and the multilevel model is the additional group level error term \(u_{0j}\). The basic multilevel model, then, is not more than an ordinary regression equation that includes an additional group-level error parameter to capture group level dependencies.

The addition of the group-level error term explicitly models variation among group means in the data. For example, if the outcome is the mean sentence length given to offenders across federal district courts, the group-level error term allows for mean sentence length to vary by federal district, thus capturing potentially important district-level differences in average punishment severity. These
differences are illustrated in Figure 4, where Panel A shows the mean sentence length pooled across a sample of ten federal districts, and Panel B shows the mean sentence length disaggregated by federal district. The figure indicates that average punishments vary across federal courts. For instance, the mean sentence length in the Northern District of Florida is about twice the average sentence in the District of Delaware. Important differences in variability in punishment also exist across federal districts, with the standard deviation in the Western District of Oklahoma being more than twice that in the Southern District of California. These group level variations are captured by the incorporation of the group-level error term in the multilevel statistical model, resulting in standard errors and statistical significance tests that are properly adjusted for the nesting of individual cases within aggregate district court groupings.

**Building the Multilevel Model**

Despite its conceptual simplicity, multilevel analysis adds a layer of analytical complexity that can quickly become cumbersome when applied to research questions involving multiple predictors across multiple levels of analysis. For this reason it is essential to build the multilevel model carefully from the ground up. There are several types of multilevel models that vary in complexity, including 1) unconditional models, 2) random intercept models, 3) random coefficient models and 4) cross-level interaction models — each adds an additional layer of complexity and provides additional information in the multilevel analysis.

**The Unconditional Model**

The first step in multilevel analysis is to investigate the necessity of using a multilevel model. This is both theoretical and statistical question. First, the research question should always dictate the methodology. Some research questions that involve multiple levels of data may be answerable with simpler and more parsimonious analytical approaches. So called “fixed effects” models, for instance, can be a simple and effective way of removing between-group variation. Including a series of dummy variables for level 2 units parcels out the level 2 variation and corrects for any intraclass correlation among nested observations. Before adopting a multilevel model, then, it is important to first make sure the research question necessitates multilevel analysis. Despite its advantages the multilevel model is not
always necessary, nor ideal. For instance, a minimum number of aggregate groupings is generally needed for multilevel analysis because a sufficient number of level 2 units is required for higher order statistical significance tests. It is also useful to begin by testing for the presence of correlated errors before turning to multilevel analysis. This can be done by estimating an ordinary regression, saving the residuals, and then conducting an analysis of variance to investigate whether or not the residuals are significantly related to group members’ ip. Significant results provide evidence that the ordinary regression assumption of independent errors is violated by the nested structure of the data.

The necessity of multilevel analysis can be further investigated through the unconditional or null model. This model is referred to as “unconditional” because it includes no predictors at any level of analysis, so it provides a predicted value for the mean which is not conditional on any covariates. It is summarized in Equation 4:

\[
\begin{align*}
\text{Level 1} & \quad Y_{ij} = \beta_{ij0} + r_{ij} \\
\text{Level 2} & \quad \beta_{ij0} = \gamma_{0j0} + u_{0j}
\end{align*}
\]

where \(Y_{ij}\) is a continuous outcome for individual \(i\) in group \(j\), estimated by the overall intercept \(\beta_{0j}\) plus an individual-level error term, \(r_{ij}\). At level 2 of the model, the intercept \(\beta_{0j}\) is modeled as a product of a level 2 intercept \(\gamma_{0j0}\) plus a group-level error term, \(u_{0j}\). The unconditional model decomposes the total variance in the outcome into two parts – an individual variance, captured by the individual-level error term, and a group variance, captured by the group-level error term. The unconditional model is therefore useful for investigating the amount of variation that exists within versus between groups. One way to

\[\text{http://sitemaker.umich.edu/group-based/optimal_design_software}\]

\[\text{Sc\ olars disagree on this point. Some advocate using multilevel models in any situation involving nested data (e.g. Gelman and Hill, 2007) while others caution its use in analyses involving relatively few level 2 units (e.g. Snijders and Bosker, 1999: 44). Although there does not seem to be widespread consensus on whether constitutes a sufficient number of groups (in part because the number of observations per grouping also matters), a general rule of thumb is to require about a dozen or so groupings before turning to multilevel analysis, at least for analyses that include level 2 predictors. This issue in part reflects concerns over statistical power in multilevel analysis, which is a product of several factors including the number of clusters, the number of observations per cluster, the strength of the intraclass correlation and the effect sizes for level 2 variables in the model, all of which will affect the decision to employ multilevel analysis. A useful optimal design software program for conducting power analysis with multilevel data is available at: http://sitemaker.umich.edu/group-based/optimal_design_software.}\]
quantify this is to calculate the intraclass correlation coefficient (ICC), which represents the proportion of the total variance that is attributable to between-group differences. The ICC is represented by Equation 5:

$$\rho = \frac{\tau_{00}}{\sigma^2 + \tau_{00}}$$  \hspace{1cm} (5)

where $\tau_{00}$ is the between-group variance estimated by the $u_{ij}$ parameter and $\sigma^2$ is the within-group variance estimated by the $r_{ij}$ parameter in Equation 4. The intraclass correlation is the ratio of between-group variance to total variance in the outcome. Larger ICCs indicate that a greater proportion of the total variance in the outcome is due to between-group differences.\(^\text{10}\) It is important to begin any multilevel analysis by estimating the unconditional model. It provides an assessment of whether or not significant between-group variation exists – if it does not, then multilevel analysis is unnecessary – and it serves as a useful baseline model for evaluating explained variance in subsequent model specifications.

Table 3 presents the results from an unconditional model examining sentence length for a random sample of federal offenders nested within U.S. district courts. The results are broken into two parts, one for the “fixed effects”, which report the unstandardized regression coefficients, and one for the “random effects”, which report variance components for the model. The overall intercept is 52.5 months indicating that the average federal sentence in this sample is just under 5 years. The level 1 variance provides a measure of within-district variation in sentence lengths and the level 2 variance provides an analogous measure for between-district variation. The significance test associated with the level 2 variance component indicates that sentence lengths vary significantly across federal district courts. Notice that the significance test uses degrees of freedom for the number of level 2 rather than level 1 units; it provides preliminary evidence that at districts

\(^{10}\) It is common in multilevel analysis for between-group variation to represent a relatively small proportion of the total variance, however, as Liska (1990) argues, this does not indicate that between group variation is unimportant.
matter in federal punishment, as Luke (2004) points out, significance tests for variance components should always be interpreted cautiously.\footnote{Variances are bounded by zero so they are not normally distributed and they are usually expected to take on non-zero values anyway so it is not always clear what a significant variance means. Although significance tests for variance components can provide a useful starting point, they should be used judiciously. It is much more useful to interpret the substantive magnitude of the variance component rather than just its statistical significance.}

In order to get a sense of the magnitude of inter-district variation in punishment, the intraclass correlation coefficient (ICC) can be calculated and the random effects can be assessed in combination with the fixed effects in Table 3. The level 2, or between group, variance is $\tau^2 = 267$ and the within-group, or individual variance is $\sigma^2 = 4,630$. Plugging these values into Equation 5 gives an ICC equal to 0.055. This indicates that 5.5% of the total variation in sentence length is attributable to between-district variation in sentencing. Similarly, the standard deviation for the between group variance component can be added and subtracted to the model intercept to provide a range of values for average sentences among districts. Adding and subtracting 16 months gives a range between 36.2 and 68.9 months, so the average sentence varies between 3 years and 5 ¾ years for one standard deviation (i.e. about two-thirds) of federal district courts. The significance test, intraclass correlation and range of average sentences all suggest important between-group variation, indicating that multilevel analysis is appropriate in this instance.

**The Random Intercept Model**

The second type of multilevel model adds predictor variables to the unconditional model and is referred to as a random intercept model because it allows the intercept to take on different values for each level 2 unit in the data. There are three types of random intercept models – models that include only level 1 predictors, models that include only level 2 predictors, and models that include both level 1 and level 2 predictors. In the first model, the focus of the multilevel analysis is on controlling for statistical dependence in clustered observations. In the second the focus is on estimating variation in group means as a function of group-level predictors, and in the third, the focus is on estimating the joint influence of both level 1 and level 2 predictors. The type of random intercept model will depend on the research.
question of interest, but it is often useful to begin by estimating the model with only level 1 predictors. This model is presented in Equation 6:

\[
\begin{align*}
\text{Level 1} & & Y_{ij} = \beta_0^{(1)} + \beta_1^{(1)} X_{ij} + r_{ij} \\
\text{Level 2} & & \beta_0^{(2)} = \gamma_0 + u_{0j}
\end{align*}
\]

where \(X_{ij}\) represents an individual level predictor added to the unconditional model in Equation 4. Again, the level 2 equation models the level 1 intercept \(\beta_0^{(1)}\) as a product of the overall mean intercept, \(\gamma_0\), and a unique level 2 error term, \(u_{0j}\). Substantively this means that the model intercept is allowed to vary randomly across level 2 units; each level 2 unit in the sample has its own group-specific intercept, just as if separate regressions were estimated for each group in the data.

Table 4 presents the results from a model examining the impact of the severity of the offense on the final sentence. In this model offense severity is centered around its grand mean (see discussion of centering below) and added to the level 1 portion of the model as a predictor of sentence length. \(\beta_1^{(1)}\) in Equation 6 represents the effect of offense severity, \(X_{ij}\), on the length of one’s sentence in federal court. It is interpreted just as it would be in an ordinary regression model – each one unit increase in offense severity increases one’s sentence length by 5.56 months. The average sentence is also allowed to vary by federal district, however. This is reflected by the level 2 variance component \(u_{0j}\) in Table 4. Both variance components now represent residuals, or left-over variation that is unaccounted for by the model.

Notice that the deviance statistic is reduced from the unconditional to the conditional model, indicating increased model fit. To better quantify the model fit, it is often useful to calculate proportionate

\[12\]

\[T \text{ e deviance statistic is equal to } -2 \times \text{ natural log of the likelihood function and serves as a measure of lack of fit between the model and the data – the smaller the deviance the better the model fit. T e inclusion of additional predictors will decrease the model deviance, and although t e deviance is not directly interpretable it is useful for comparing alternative model specifications to one another (Luke, 2004). T e difference in deviance statistics for two models is distributed as a chi-square distribution with degrees of freedom equal to the difference in the number of parameters in the two models. Multilevel models are typically fit with maximum likelihood estimation but t is can be done using either full maximum likelihood (ML) or restricted maximum likelihood (REML). Both estimators will produce identical estimates of the fixed effects, but REML will produce variance estimates that are less biased than ML when the number of level 2 units is relatively small (see Kreft and DeLeeuw, 1998: 131-133; Snijders and Bosker, 1999: 88-90). REML is useful for testing two nested models that differ only in their random effects (e.g. an}
reduction of error (PRE) measures at approximate $R^2$ statistics for explained variance at each level of analysis. Equation 7 provides the formulas for these calculations:

$$R^2_{\text{Level 1}} = \frac{\sigma^2_{\text{unc}} - \sigma^2_{\text{cond}}}{\sigma^2_{\text{unc}}}$$

$$R^2_{\text{Level 2}} = \frac{\tau^2_{\text{unc}} - \tau^2_{\text{cond}}}{\tau^2_{\text{unc}}}$$

Where explained variation at level 1 is calculated by examining the reduction in level 1 variance relative to the total variance from the unconditional model reported in Table 3. The unconditional estimate of level 1 variance was 4,639 and the conditional (i.e. controlling for offense severity) estimate is 2,228.7. The difference (2,401.3) divided by the total unconditional variance (4,630) provides an $R^2$ estimate of .519, so offense severity explains over 50% of the variance in sentence lengths among federal offenders.

The inclusion of level 1 predictors can also explain between-district variation at level 2 of the analysis. This is because there may be important differences in offense severity across districts, with some districts systematically facing more serious crime than others. Explained variation at level 2 is calculated by examining the reduction in level 2 variance from the unconditional to the conditional model. The unconditional estimate for between-district variation was 267.1 and the conditional estimate is 93.2. The difference (173.9) divided by the total (267.1) provides an estimate of explained variation at level 2 equal to .651. This indicates that 65% of inter-district variation in sentences is due to the fact that districts vary in the severity of the crimes they face, or 65% of district variation is attributable to compositional differences in offense severity.13

The random intercept model can be expanded to also include a level 2 predictor as in Equation 8:

$$R^2_{\text{Total}} = \frac{(\sigma^2_{\text{unc}} - \tau^2_{\text{cond}}) - (\sigma^2_{\text{cond}} - \tau^2_{\text{cond}})}{\sigma^2_{\text{unc}} + \tau^2_{\text{unc}}}$$

13 These basic formulas for explained variance are simple to apply and often quite useful, but in some circumstances it is possible for the inclusion of additional predictors to result in smaller or even negative values for explained variance (Snijders and Bosker, 1999: 99-100). Slightly more complicated alternative formulas are also available that include adjustments for the average number of level 1 units per level 2 unit (see e.g. Luke, 2004: 36). Total explained variance at both levels of analysis can be computed using the combined formula:
Group mean differences in the intercept, $\beta_{0j}$, are now modeled as a product of a group-level predictor, $W_j$, with $\gamma_{01}$ representing the effect of the level 2 covariate on the outcome of interest. Level 2 predictors can take several forms including aggregate, structural or global measures (see Table 2). Results for the model including the individual level 1 predictor (offense severity) and the level 2 predictor (Southern location) are presented in Table 5. The effect of offense severity remains essentially unchanged, but districts in the Southern sentence offenders to an additional 7.1 months of incarceration. Although level 1 variables can explain variation at both levels of analysis, level 2 variables can only explain between-group variation at level 2. Accordingly, the level 2 predictor Southern does not alter the level 1 variance estimate but it does reduce the level 2 variance from 93.2 to 82.4. This is a reduction of 11.6% so Southern location accounts for just under 12% of the residual level 2 variance after controlling for offense severity. Equation 8 includes only one level 1 and one level 2 predictor, but the model can be easily expanded to include multiple predictors at both levels of analysis. Although the random intercept model allows the group means to vary as a product of level 2 predictors, it assumes that the effects of the level 1 predictors are uniform across level 2 units. This assumption can be investigated and if it is violated then a random coefficient model may be more appropriate.

**THE RANDOM COEFFICIENT MODEL**

The random coefficient model builds upon the random intercept model by allowing the effects of individual predictors to also vary randomly across level 2 units. That is, the level 1 slope coefficients are allowed to take on different values in different aggregate groupings. The difference between the random intercept and random coefficient model is graphically depicted in Figure 5, where each line represents the effect of some $X$ on $Y$ for 3 hypothetical groupings. In the random intercept model, the slopes are constrained to be the same for all 3 groups but the intercepts are allowed to be different. In the random coefficient model, both the intercepts and slopes are allowed to differ across the 3 groups – the effect of $X$
on \( Y \) varies by group. Mathematically, the random coefficient model (with a single level 1 predictor) is represented by Equation 9:

\[
\begin{align*}
\text{Level 1} & \quad Y_{ij} = \beta_0 + \beta_{ij} X_{ij} + r_{ij} \\
\text{Level 2} & \quad \beta_{ij} = \gamma_{0j} + u_{0j} \\
& \quad \beta_{1j} = \gamma_{1j} + u_{1j}
\end{align*}
\]  

(9)

where the key difference from Equation 6 is the addition of the new random error term \( u_{1j} \) associated with the effect of \( X \) on \( Y \). That is, the slope coefficient is modeled with a random variance component, allowing it to take on different values across level 2 units. For instance, the treatment effect of an after-school delinquency program might vary by school context, being more effective in some schools than others (Gottfredson et al. 2007). The random coefficient model can capture this type of between-group variation in the effect of the independent variable on the outcome of interest.

The decision to specify random coefficients should be based on both theory and empiricism. Regarding federal sentencing data, it might make theoretical sense to investigate variations in the effect of offense severity across courts because some literature suggests perceptions of crime seriousness involve a relative evaluation by court actors (Emerson, 1983). Definitions of “serious” crime might be different in different court contexts. To test this proposition, the deviance statistics can be compared for two models, one with offense severity specified as a fixed (i.e. non-varying) coefficient as reported in Table 4 and one with it specified as a random coefficient as in Table 6. The deviance for the random intercept model is 263,876 and the deviance for the random coefficient model is 262,530. The difference produces a chi-square statistic of 1,346 with 2 degrees of freedom which is highly significant.14 The null hypothesis can therefore be rejected in favor of the random coefficient model.

\[14\] The difference in the number of parameters is equal to 2 because the addition of the random coefficient introduces both an additional variance component and an additional covariance component to the model:

\[
\begin{bmatrix}
\tau_{0j} \\
\tau_{1j}
\end{bmatrix}
\]

where \( \tau_{1j} \) is the new variance associated with the random coefficient \( \beta_{ij} \). Because the models only differ in their random components, REML estimation is used for this comparison.
Additional evidence in support of the random coefficient model is provided by the significantly significant p-value for the $u_{ij}$ parameter in Table 6. This suggests there is significant variation in the effect of offense severity across district courts. To quantify this effect, the standard deviation (s.d.$=1.2$) for the random effect can be added and subtracted to the coefficient ($b=5.7$) for offense severity. This suggests that each unit increase in offense severity increases one’s sentence length between 4.5 and 6.9 months for one standard deviation (i.e. about two-thirds) of federal district courts. One final diagnostic tool for properly specifying fixed and random coefficients is to compare differences between model-based and robust standard errors.\(^{15}\) Discrepancies between the two likely indicate model misspecification, such as level 1 coefficients that should be specified as random rather than fixed effects.

To demonstrate, Table 7 provides a comparison of an OLS, random intercept and random coefficient model, along with a pictorial representation of each. As expected, the standard errors in the OLS model are underestimated. The standard error for the model intercept, for instance, increases from .30 to 1.10 from the OLS to the random intercept model. Examining the robust standard errors in the random intercept model suggests there may be a problem – the robust standard error for offense severity is more than 6 times as large as its model-based standard error. This is consistent with earlier results that suggested significant variation exists in the effect of offense severity across districts. Allowing for this variation in the random coefficient model produces model-based and robust standard error estimates for offense severity that are identical. Large differences in robust standard errors can serve as a useful diagnostic tool for identifying misspecification in the random effects portion of the multilevel model.

These diagnostic approaches, along with theoretical considerations, could be used to gradually build the random effects portion of the random coefficient model. Ecological predictors can also be included at level 2 of the random coefficient model. Table 8 reports the results for the random coefficient model.

---

\(^{15}\) Robust standard errors are standard errors that are adjusted to account for possible violations of underlying model assumptions regarding error distributions and covariance structures (see Raudenbus and Bryk, 2002: 276). In the case of multilevel models, these violations can lead to misestimated standard errors that result in faulty statistical significance tests. Robust standard errors provide estimates that are relatively insensitive to model misspecifications, but because the calculation of robust standard errors relies on large sample properties, they could only be used when the number of level 2 units is relatively large.
model adding Southern location as a level 2 predictor. Notice that the estimated effect of Southern is less in the random coefficient model in Table 8 than it was in the random intercept model in Table 5. This highlights the importance of properly specifying the random effects portion of the multilevel model – changes in the random effects at level 1 can alter the estimates for both level 1 and level 2 predictors.

Often times the final multilevel model will include a mixture of fixed and random coefficients, which is why it is sometimes called the “mixed model.” Equation 10 provides an example of a mixed model with two level 1 predictors and 1 level 2 predictor:

\[
\begin{align*}
\text{Level 1: } & \quad Y_{ij} = \beta_0 + \beta_{1j}X_{1ij} + \beta_{2j}X_{2ij} + r_{ij} \\
\text{Level 2: } & \quad \beta_{0j} = \gamma_{00} + \gamma_{01}W_j + u_{0j} \\
& \quad \beta_{1j} = \gamma_{10} + u_{1j} \\
& \quad \beta_{2j} = \gamma_{20}
\end{align*}
\] (10)

In this mixed model, the effect of the first independent variable \(X_{1ij}\) is allowed to have varying effects across level 2 units because its coefficient \(\beta_{1j}\) in level 2 of the model includes the random error term \(u_{1j}\). It is this error variance that allows the effect of \(X_{1ij}\) to take on different values for different level 2 units. The effect of the second level 1 predictor \(X_{2ij}\), however, does not include a random error variance. Its effect is therefore constrained to be “fixed” or constant across level 2 units. Although measures of explained variance can be calculated for random coefficient and mixed models, these calculations do not account for the additional variance components introduced by the random effects, so it is advisable to perform these calculations on the random intercept only model (see e.g. Snijders and Bosker, 1999: 105).

**The Cross-Level Interaction Model**

Like ordinary regression models, multilevel models can be further expanded to include interaction terms. These can be incorporated in three basic ways. Individual interactions can be included from cross-product terms for individual level predictors. For instance, victim race and police officer race might be interacted in a study of police use of force (Lawton, 2007). Ecological interactions can also be included using level 2 predictors. Ethnic heterogeneity could be interacted with low socioeconomic
conditions at the neighborhood level, for instance, in a study on risk of victimization (Miethe and McDowall, 1993). Finally cross-level interactions can be included to specify cross-product terms across levels of analysis. For instance, the effects of parental monitoring on problem behavior at the individual level might be expected to vary among neighborhoods with different levels of collective efficacy (Rankin and Quane, 2002). This type of interaction is unique to multilevel analysis so it deserves additional explanation. Equation 11 specifies a cross-level interaction model with 1 individual predictor, 1 ecological predictor and the cross-level interaction between them:

\[
\begin{align*}
\text{Level 1} & \quad Y_{ij} = \beta_0 + \beta_1 X_{1ij} + r_{ij} \\
\text{Level 2} & \quad \beta_0 = \gamma_0 + \gamma_1 W_j + u_{0j} \\
& \quad \beta_1 = \gamma_2 + \gamma_3 W_j + u_{1j}
\end{align*}
\]

(11)

This model adds the level 2 predictor \( W_j \) to the level 2 equation for \( \beta_1 \), so \( W_j \) is now being used to explain variation in the effect of \( \beta_1 \) across level 2 units, with a new parameter \( \gamma_3 \) representing the cross-level interaction between \( X_{1ij} \) and \( W_j \). Cross-level interactions are useful for answering questions about why individual effects vary across level 2 units; they explicitly model variation in level 1 random coefficients as a product of level 2 group characteristics. Table 9 provides results from a cross-level interaction model examining the conditioning effects of Southern court location on the individual effect of offense severity for federal sentence length. The positive interaction effect indicates that offense severity as a stronger effect on sentence length in Southern districts than in non-Southern districts. Figure 6 graphs this relation for values one standard deviation below and above the mean and suggests that the cross-level interaction is statistically significant its substantive magnitude

---

16 Depending on the statistical program used, these interactions may or may not be able to be created in the multilevel interface. With HLM, both individual interactions and ecological interactions must be created and all centering adjustments must be made before importing them into the HLM program.

17 Although conceptually the goal of cross-level interactions is usually to explain significant variation in the effects of level 1 random coefficients across level 2 units, there are instances when theory may dictate examining cross-level interactions for fixed coefficients at level 1 as well. Significant cross-level interactions may emerge involving fixed level 1 coefficients because the significance tests for the cross-level interactions are more powerful than the significance tests produced for random coefficient variance components (Snijders and Bosker, 1999: 74-75).
is fairly modest. As with other multilevel models, cross-level interaction models can easily be extended to the case of multiple predictors at both individual and group levels of analysis, although care should be taken when including multiple interactions in the same model.

ADDITIONAL CONSIDERATIONS

The preceding examples offer only a rudimentary introduction to the full gamut of multilevel modeling applications but they provide a basic foundation for doing more complex multilevel analysis. The multilevel model can be further adapted to account for additional data complexities that commonly arise in criminological research, including centering conventions, nonlinear dependent variables, and additional levels of analysis. These issues are briefly highlighted below although interested readers should consult comprehensive treatments available elsewhere (e.g. Raudenbus and Bryk, 2002; Luke, 2004; Goldstein, 1995; Snijders and Bosker, 1999; Kreft and de Leeuw, 1998; Gelman and Hill, 2007).

CENTERING IN MULTILEVEL ANALYSIS

In multilevel models, the centering of variables takes on special importance. Centering, or reparameterization, involves simple linear transformations of the predictor variables by subtracting a constant such as the mean of $X$ or $W$. Centering in the multilevel framework is no different than in ordinary multiple regression, but it offers important analytical advantages, making model intercepts more interpretable, making main effects more meaningful when interactions are included, reducing collinearity associated with polynomials and interactions, facilitating model convergence in nonlinear models, and simplifying graphical displays of output. Estimates of variance components may also be affected by the centering convention because random coefficients often involve heteroskedastic error variances that depend on the value of $X$ at which they are evaluated (Hox, 2002).

In general, there are main centering options are available: no centering, grand-mean centering and group-mean centering. No centering leaves the variable untransformed in its original metric. Although this can be a reasonable approach depending on how the variables are measured, it is usually advisable to employ a centering convention in multilevel analyses for the reasons stated above. The simplest centering convention is grand-mean centering which involves subtracting the overall mean, or the pooled average,
from each observation in the data. The subtracted mean, then, becomes the new zero point so positive values represent scores above the mean and negative values represent scores below the mean.

Grand mean centering is represented as \((X_{ij} - \bar{X}_j)\) where \(X_{ij}\) is the value of \(X\) for individual \(i\) in group \(j\) and \(\bar{X}_j\) is the grand mean pooled across all observations in the data. Grand mean centering is often useful and rarely detrimental so it offers a good standard centering convention. It only affects the parameter estimates for the model intercept, making the value of the intercept equal to the predicted value of \(Y\) when all variables are set to their means. This allows the intercept in a grand-mean centered model to be interpreted as the expected value for the “average” observation in the data.

The alternative to grand mean centering is group mean centering, represented as \((X_{ij} - \bar{X}_j)\), where \(X_{ij}\) is still the value of \(X\) for individual \(i\) in group \(j\) but \(\bar{X}_j\) is now the group-specific mean, so individuals in different level 2 groups have different values of \(\bar{X}_j\) subtracted from their scores. Group-mean centering is more complicated than grand-mean centering because it fundamentally alters the meaning and interpretation of both the parameter estimates and the variance components in the multilevel model. It should therefore be used selectively. Luke (2004: 52), for instance, recommended that “one should use group-mean centering only if there are strong theoretical reasons to do so.”

In general, centering is always a good idea when a variable has a non-meaningful zero point. For example, it would make little sense to include the UCR crime rate as a predictor variable without first centering it. Otherwise the model intercept would represent the predicted value of \(Y\) when the crime rate was equal to 0, which is clearly unrealistic. Even when variables do have meaningful zero points it is often useful to center them. For instance, often times it is even useful to center dummy variables. Adjusting for the grand mean essentially removes the influence of the dummy variable so the model intercept represents the expected value of \(Y\) for the “average” of the at variable rather than the reference

---

18 Some exceptions to this general rule include growth curve modeling with longitudinal data, where the focus is often on separating within and between group regression effects, or research questions involving “frog pond” effects where the theoretical interest is on individual adaptation to one’s specific environment rather than the average effects of individual predictors on the outcome of interest.
category. Similar centering rules apply for ecological variables as for individual level variables, but the important point is that centering decisions should be made *a priori* based on theoretical considerations regarding the desired meaning of model parameters. A number of more detailed treatments offer further detail on the merits and demerits of grand-mean and group-mean centering conventions for multilevel analysis (e.g. Kreft, 1995; Kreft et al. 1995; Longford, 1989; Raudenbus, 1989; Paccagnella, 2006).

**GENERALIZED MULTILEVEL MODELS**

The examples up to this point all assume a normally distributed continuous dependent variable. Often times, however, criminological research questions involve nonlinear or discrete outcomes, such as binary, count, ordinal or multinomial variables. When this is the case, the multilevel model must be adapted by transforming the dependent variable. For example, dichotomous dependent variables are common in research on crime and justice; whether or not an offender commits a crime, the police make an arrest, or a judge sentences to incarceration all involve binary outcomes (e.g. Eitle et al. 2005; Griffin and Armstrong, 2003; Johnson, 2006). In these cases, the discrete dependent variable often violates assumptions of the general linear model regarding linearity, normality, and homoskedasticity of level 1 errors (Raudenbus and Bryk, 2002). Moreover, because the outcome is bound by 0 and 1, the fitted linear model is likely to produce nonsensical and out of range predictions.

None of these issues are unique to multilevel analysis and the same adjustments used in ordinary regression can be applied to the multilevel model, although some important new issues arise in the multilevel context. Collectively these types of models are labeled generalized hierarchical linear models (GHLM) or just generalized multilevel models, because they provide flexible generalizations of the ordinary linear model. The basic structure of the multilevel model remains the same but the sampling distribution changes. For illustrative purposes, the case of multilevel logistic regression with a dichotomous outcome is illustrated. Equation 12 provides the formula for the unconditional two-level multinomial model using the binomial sampling distribution and the logit link function.

---

19 The “link function” can be thought of as a mathematical transformation that allows the non-normal dependent variable to be linearly predicted by the explanatory variables in the model.
Logit Link Function

\[ \eta_{ij} = \ln \left( \frac{1 + p}{1 - p} \right) \]

Level 1
\[ \eta_{ij}^* = \beta_{0j} \]
Level 2
\[ \beta_{1j} = \gamma_{00}^* \]

In this formulation, \( p \) is the probability of the event occurring and \((1-p)\) is the probability of the event not occurring. \( p \) over \((1-p)\), then, represents the odds of the event and taking the natural log provides the log odds. The dependent variable for the dichotomous outcome is therefore the log of the odds of success for individual \( i \) in group \( j \), represented by \( \eta_{ij} \). The multinomial logistic model is probabilistic, capturing the likelihood of the event occurring. Whereas the original binary outcome was constrained to be \( 0 \) or \( 1 \), \( p \) is allowed to vary in the interval \( 0 \) to \( 1 \), and \( \eta_{ij} \) can take on any real value. In this way, the logistic link function transforms the discrete outcome into a continuous range of values. The level 2 model is identical to that for the continuous outcome presented in Equation 4, but \( \gamma_{00}^* \) now represents the average log odds of the event occurring across all level 2 units. Equation 13 provides the random coefficient extension of the multilevel logistic model with one random level 1 coefficient and one level 2 predictor:

Level 1
\[ \eta_{ij} = \beta_{0j} + \beta_{1j} X_{1ij} \]
Level 2
\[ \beta_{0j} = \gamma_{00}^* + \gamma_{01}^* W_j + u_{0j} \]
\[ \beta_{1j} = \gamma_{10}^* + u_{1j} \]

where \( \eta_{ij} \) still represents the log of the odds of success and all other parameters are the same as previously described.

Notice that in both equations 12 and 13 there is no level 1 variance component included in the multilevel logistic model. This is because the level 1 variance is heteroskedastic and completely determined by the value of \( p \), it is therefore unidentified and not included in the model. This means that the standard formulas for the intraclass correlation and explained variance at level 1 cannot be directly applied to the case of a binary dependent variable. Also, most software packages do not provide

---

20 The level 1 variance in the case of a logistic model is equal to \( p(1-p) \) where \( p \) is the predicted probability for the level 1 model. The level 1 variance therefore varies as a direct product of the value of \( p \) at which the model is
deviance statistics for nonlinear multilevel models. This is because generalized linear models typically rely on “penalized quasi likelihood” (PQL), rather than full or restricted maximum likelihood. This involves a double-iterative process that provides only a rough approximation to the likelihood function on which the deviance is based. In most cases, this means that other methods, such as theory, significance tests for variance components, and robust standard error comparisons must be relied on to properly specify random coefficients in level 1 of the multilevel logistic model.21

A third complication involving multilevel models with nonlinear link functions is that two sets of results are produced, one labeled “unit-specific” results and one labeled “population-averaged” results. Unit-specific results are estimated holding constant the random effects in the model, whereas population-averaged results are averaged across all level 2 random effects (see Raudenbus and Bryk, 2002: 301). This means that unit-specific estimates model the dependent variable conditional on the random effects in the model, whereas population-averaged results provide estimates of how the level 1 and level 2 variables affect outcomes within level 2 units. Population-averaged estimates, on the other hand, provide the marginal expectation of the outcome averaged across the entire population of level 2 units. If you wanted to know how much an after-school program reduces delinquency for one student compared to another in the same school, then the unit-specific estimate would be appropriate. If you wanted to summarize the average effect of the after-school program on delinquency across all schools, then the population-averaged estimate would be preferred. In short, which results to report depends on the research question at hand.22 For example, work on racial evaluated. Although multilevel logistic models do not include a level 1 variance term, some alternatives approaches are available for estimating intraclass correlations. For example, Snijders and Bosker, (1999: Chapter 14) discuss reconceptualizing the level 1 model as a latent variable $Z_{ij} = \eta_f + r_{ij}$ in which the level 1 error term is assumed to have a standard logistic distribution with a mean of 0 and variance of $\pi^2/3$. In that case, the intraclass correlation can be calculated as $\rho = \tau_{00}/(\tau_{00} + \pi^2/3)$. This formulation requires the use of the logit link function and relies on the assumption that the level 1 variance follows the logistic distribution. Alternative formulations have also been discussed for the probit link function using the normal distribution (see e.g. Gelman and Hill, 2007: 118).

21 PQL estimates are usually sufficient, but tests for random effects based on the PQL likelihood function in models with discrete outcomes may be unreliable, especially for small samples. Alternative full maximum estimators, such as Laplace estimation, are available in some software packages and can be used to test for random effects using deviance, but this can be computationally intensive.

22 These estimates are often similar but their differences will widen as between-group variance increases and the probability of the outcome becomes farther away from .50 (Raudenbus and Bryk, 2002: 302). In the case of continuous dependent variables the unit-specific and population estimates are identical so this distinction only arises in the case of nonlinear dependent variables.
disparity in sentencing typically reports unit-specific estimates because the focus is on the effect of an offender’s race relative to other offenders sentenced in the same court (e.g., Ulmer and Johnson, 2004). Recent work integrating routine activities and social disorganization theory, on the other hand, reports population average estimates because in their words of the authors “our research questions concern aggregate rates of delinquency and unstructured socializing” among all schools (Osgood and Anderson, 2004: 534).

Table 10 reports the unit-specific results with robust standard errors for a random coefficient model examining the likelihood of imprisonment in federal court. The level 1 predictor is the severity of the offense and the level 2 predictor is Southern location. Offense severity exerts a strong positive effect on the probability of incarceration. The coefficient of .26 represents the change in the log odds of imprisonment for a one-unit increase in severity. To make it more interpretable, it is useful to transform the raw coefficient into an odds ratio. Because the left-hand side of Equation 13 represents the log of the odds, we obtain the odds by taking the antilog, in this case \( e^{.26} = 1.29 \). For each unit increase in the severity of the crime committed, the odds of incarceration increases by a factor of .29 or 29%.23 The coefficient for Southern in the model is not statistically significant, suggesting there is no statistical evidence that offenders are more likely to be incarcerated in Southern districts. Turning to the random effects, the level 2 intercept indicates that significant inter-district variation in incarceration remains after controlling for severity and Southern location, and that significant variance exists in the effect of offense severity across districts. Adding the standard deviation to the fixed effect for severity provides a range of coefficients between .20 and .32. Transformed into odds ratios, this means that the effect of offense severity varies between 1.22 and 1.38, so offense severity increases the odds of incarceration between 22% and 38% across one standard deviation (i.e., about two-thirds) of federal districts.

\[ p_{ij} = \frac{e^{\gamma_{00} + \gamma_{20} W_j + \gamma_{10} X_{ij}}}{1 + e^{\gamma_{00} + \gamma_{20} W_j + \gamma_{10} X_{ij}}}, \]  

\[ \bar{p}_{ij} = \frac{e^{\gamma_{00}}}{1 + e^{\gamma_{00}}}. \]

23 The individual probability of incarceration for individual \( i \) in court \( j \) can be calculated directly using the formula:
As with linear multilevel models, generalized multilevel models can be easily extended to the case of multiple predictors at both levels of analysis. In general, similar transformations can be applied for multilevel Poisson, binomial, ordinal and multinomial models by simply applying different link functions to different sampling distributions (see e.g. Raudenbus and Bryk, 2002: Chapter 10; Luke, 2004: 53-62). In this way, the basic linear multilevel model can be easily generalized to address a variety of criminological research questions involving different types of discrete dependent variables.

**Three-Level Multilevel Models**

The basic two-level multilevel linear and generalized models can also be extended to incorporate more complicated data structures that span three or more levels of analysis. The basic logic of the multilevel model is the same, but additional error variances are added for each additional level of analysis. The three-level unconditional model for a linear dependent variable is presented in Equation 14:

\[
\begin{align*}
\text{Level 1} & \quad Y_{ijk} = \pi_{0jk} e_{ijk} \\
\text{Level 2} & \quad \pi_{0jk} = \beta_{00k} r_{0jk} \\
\text{Level 3} & \quad \beta_{00k} = \gamma_{000} u_{00k}
\end{align*}
\]

Equate subscript indexes level 1 (e.g. students), subscript indexes level 2 (e.g. classrooms) and subscript indexes level 3 (e.g. schools). Now level 1 coefficients are represented with \( \pi \)'s, level 2 coefficients with \( \beta \)'s and level 3 coefficients with \( \gamma \)'s, but the three-level structure is purely notational convenience, so it can be simplified through substitution to produce the equivalent but simpler combined model in Equation 15:

\[
Y_{ijk} = \gamma_{000} e_{ijk} r_{0jk} u_{00k}
\]

Equation 14 and 15 are substantively identical and it becomes clear in the combined model that the outcome \( Y_{ijk} \) is modeled as a simple product of an overall intercept \( \gamma_{000} \) plus three different error terms, one for each level of analysis. As in the case of the two-level unconditional model, the three-level model...

---

24 Some important differences emerge in these other contexts, for example, overdispersion frequently occurs in Poisson models for count data, so it is common to incorporate an additional overdispersion parameter in the level 1 model for this type of generalized linear model (see Raudenbus and Bryk, 2002: 295; Gelman and Hill, 2007: 114).

25 Some software packages like HLM are currently limited to three levels of analysis, but other programs (e.g. WLwiN) can analyze up to 10 separate levels of analysis.
parcels the variation in the outcome across levels of analysis. Similar estimates can therefore be calculated for intraclass correlation coefficients, but in the case of the ree-level model, there are separate r coefficients for level 2 and level 3 of the analysis.

In the federal court system, cases are nested within district courts but district courts are also nested within circuit courts, which serve as courts of appeal and play an important role in establishing federal case law. Table 10 provides the results from a three-level unconditional model examining federal sentence lengths for the same random sample of 25,000 cases, nested within 89 federal districts, and within 11 federal circuits. The level 2 and level 3 variance components are highly significant, indicating that federal sentences vary significantly across both district and circuit courts. The intraclass correlation coefficients suggest that about 3.5% of the total variation sentencing is between federal districts and another 1.7% between circuit courts. Notice that some of the between-district court variation from the two-level model in Table 3 is now being accounted for by level 3 of the analysis.

As with the two-level model, predictors can be added at each level of analysis. That is, individual predictors can be added at level 1, district court predictors can be added at level 2, and circuit court predictors can be added at level 3. Similar steps can then be taken to identify random coefficients as with the two-level model, but care should be exercised in this process because error structures for three-level models can quickly become complicated. This is because Level 1 variables can be specified as random coefficients at both level 2 and level 3 of the analysis. Moreover, Level 2 coefficients can also be specified as random effect at level 3 of the analysis. Cross level interactions can occur between levels 1 and 2, levels 1 and 3, or levels 2 and 3. The various possible model specifications can quickly become unwieldy so it is particularly important in three-level models to exercise care in first identifying hypothesized effects of interest and then properly specifying the model to capture them.

---

26 The formula for the level 2 intraclass correlation is $\rho_{level2} = \frac{\tau_\pi}{\sigma^2}$, where $\sigma^2$ is the level 1 variance, $\tau_\pi$ is the level 2 variance, and $\tau_\beta$ is the level 3 variance. The formula for the level 3 intraclass correlation is $\rho_{level3} = \frac{\tau_\beta}{\sigma^2}$ (see Raudenbus and Bryk, 2002: 230).
Equation 16 provides an example of a basic three-level mixed model with one level 1 predictor, $Z_{ijk}$, specified as randomly varying across both level 2 and level 3, one level 2 predictor, $X_{jk}$, fixed at level 3, and no level 3 predictors:

\[
\begin{align*}
\text{Level 1} & : Y_{ijk} = \pi_{0jk} + \pi_{1jk}Z_{ijk} + e_{ijk} \\
\text{Level 2} & : \pi_{0jk} = \beta_{00k} + \beta_{01k}X_{jk} + r_{0jk} \\
& : \pi_{1jk} = \beta_{10k} + r_{1jk} \\
\text{Level 3} & : \beta_{00k} = \gamma_{00k} + u_{00k} \\
& : \beta_{01k} = \gamma_{01k} \\
& : \beta_{10k} = \gamma_{10k} + u_{10k}
\end{align*}
\] (16)

The subscripts and multiple levels can easily become confusing so it is often useful to examine the combined model substituting levels 2 and 3 into the level 1 equation. Equation 17 provides this reformulation with the fixed effects, or regression coefficients, isolated with parent eses and the random effects, or error variances, isolated with brackets:

\[
Y_{ijk} = \left(\gamma_{000} + \gamma_{001}Z_{ijk} + \gamma_{010}X_{jk}\right) [e_{ijk} \quad r_{0jk} \quad u_{00k} \quad r_{1jk}Z_{ijk} \quad u_{10k}Z_{ijk}]
\] (17)

$\gamma_{000}$ is the overall model intercept, and $\gamma_{001}$ and $\gamma_{010}$ are the regression effects for the level 1 and level 2 predictors respectively. As in the unconditional model, $e_{ijk}$, $r_{0jk}$, and $u_{00k}$ are the level 1, 2 and 3 error variances, and the new error terms $r_{1jk}Z_{ijk}$ and $u_{10k}Z_{ijk}$ indicate the effect of the level 1 variable, $Z_{ijk}$, is allowed to vary across both level 2 and level 3 units.

Estimating this model with data on federal sentence lengths produces the output in Table 11. These results report model-based rather than robust standard errors because the highest level of analysis includes only 11 circuit courts. The effect of offense severity is essentially the same, increasing sentence length by about 5.7 months, but the effect for Southern location has been attenuated and is now only marginally significant. This likely reflects the fact that some of the district variation is now being accounted for by the circuit level of analysis. The random effects in Table 11 support this interpretation. The level 2 variance component is smaller than it was in the two-level model reported in Table 8. Notice also that there are two variance components associated with offense severity because its effect is allowed...
to vary both across district and circuit courts. The magnitude of these variance components indicates there is more between-district than between-circuit variation in the effect of offense severity, but both are highly significant. Although conceptually the three-level multilevel model represents a straightforward extension of the two-level model, in practice care needs to be exercised to avoid exploding complexity (for recent examples using 3 level models see Duncan et al., 2003; Johnson, 2006; Wright et al. 2007).

**SUMMARY AND CONCLUSIONS**

Multilevel models represent an increasingly popular analytical approach in the field of criminology. According to a recent analysis by Gary Kleck (2006), between 5% and 6% of empirical research papers in top criminology journals utilize multilevel modeling techniques; interestingly, though, 14% of these were published in the flagship journal for the field, *Criminology*. Given the omnipresence of multilevel research questions in criminology, the use of multilevel analysis will continue to gain prominence in the field. Because multilevel models provide a sophisticated approach for integrating multiple levels of analysis, they represent an important opportunity to expand theoretical and empirical discourse across a variety of criminological domains. Multilevel models have already been used to study a rich diversity of topics, from examinations of self-control (Hay and Forrest, 2006; Doherty, 2006; Wright and Beaver, 2005) and strain theory (Slocum et al. 2005) to life course perspectives (Horney et al. 1995; Sampson et al. 2006) and analyses of violent specialization (Osgood and Scheck, 2007) – from crime victimization (Xie and McDowall, 2008; Wilcox et al. 2007), policing (Rosenfeld et al. 2007; Warner, 2007) and punishment outcomes (Kleck et al. 2005; Bontrager et al. 2005; Johnson, 2005; 2006) to post-release recidivism (Kubrin and Stewart, 2005; Chiricos et al. 2007; Mears et al. 2008) and program evaluations (Gottfredson et al. 2007; Esbensen et al. 2001) – across a broad range of criminological topic areas, multilevel models have proven to be invaluable tools.

Despite their many applications, though, the old adage that “A little bit of knowledge can be a dangerous thing” applies directly to multilevel modeling. Modern software packages make estimating multilevel models relatively simple, but the fully specified multilevel model often contains complicated error structures that can easily be misspecified. Moreover, these complexities can sometimes result in
instability in parameter estimates. This is particularly the case for ecological predictors and for tree-level and generalized linear models. For instance, it is common for ecological predictors to have shared variance (Land et al. 1990), so inclusion or elimination of one predictor can often affect the estimates for other predictors in the model. It is therefore essential that the final model be carefully constructed from the ground up, performing model diagnostics to test for misspecification, investigating problematic collinearity and examining alternative models to ensure that the final estimates are robust to minor alterations in model specification.

Although this chapter provides a basic overview of multilevel models, it is important to note that it does not cover many of their advanced applications such as longitudinal data analysis, growth curve modeling, time series data, latent variable analysis, meta-analytical techniques or analysis of cross-classified data. Beyond situations where individuals are influenced by social contexts, multilevel data commonly characterizes these and many other criminological enterprises. As a discipline, we are just beginning to incorporate the full range of applications for multilevel statistical models in the study of crime and punishment. The goals of this chapter were simply to introduce the reader to the basic multilevel model, to emphasize the ways in which it is similar to and different from the ordinary regression model, to provide some brief examples of different types of multilevel models and to demonstrate how they can be estimated within the context of jurisdictional variations in federal criminal punishments across court contexts.
